

# Chapter 1

## Data Mining

In this introductory chapter we begin with the essence of data mining and a discussion of how data mining is treated by the various disciplines that contribute to this field. We cover “Bonferroni’s Principle,” which is really a warning about overusing the ability to mine data. This chapter is also the place where we summarize a few useful ideas that are not data mining but are useful in understanding some important data-mining concepts. These include the TF.IDF measure of word importance, behavior of hash functions and indexes, and identities involving  $e$ , the base of natural logarithms. Finally, we give an outline of the topics covered in the balance of the book.

### 1.1 What is Data Mining?

The most commonly accepted definition of “data mining” is the discovery of “models” for data. A “model,” however, can be one of several things. We mention below the most important directions in modeling.

#### 1.1.1 Statistical Modeling

Statisticians were the first to use the term “data mining.” Originally, “data mining” or “data dredging” was a derogatory term referring to attempts to extract information that was not supported by the data. Section 1.2 illustrates the sort of errors one can make by trying to extract what really isn’t in the data. Today, “data mining” has taken on a positive meaning. Now, statisticians view data mining as the construction of a *statistical model*, that is, an underlying distribution from which the visible data is drawn.

**Example 1.1:** Suppose our data is a set of numbers. This data is much simpler than data that would be data-mined, but it will serve as an example. A statistician might decide that the data comes from a Gaussian distribution and use a formula to compute the most likely parameters of this Gaussian. The mean

and standard deviation of this Gaussian distribution completely characterize the distribution and would become the model of the data.  $\square$

### 1.1.2 Machine Learning

There are some who regard data mining as synonymous with machine learning. There is no question that some data mining appropriately uses algorithms from machine learning. Machine-learning practitioners use the data as a training set, to train an algorithm of one of the many types used by machine-learning practitioners, such as Bayes nets, support-vector machines, decision trees, hidden Markov models, and many others.

There are situations where using data in this way makes sense. The typical case where **machine learning is a good approach is when we have little idea of what we are looking for in the data**. For example, it is rather unclear what it is about movies that makes certain movie-goers like or dislike it. Thus, in answering the “Netflix challenge” to devise an algorithm that predicts the ratings of movies by users, based on a sample of their responses, machine-learning algorithms have proved quite successful. We shall discuss a simple form of this type of algorithm in Section 9.4.

On the other hand, **machine learning has not proved successful in situations where we can describe the goals of the mining more directly**. An interesting case in point is the attempt by WhizBang! Labs<sup>1</sup> to use machine learning to locate people’s resumes on the Web. It was not able to do better than algorithms designed by hand to look for some of the obvious words and phrases that appear in the typical resume. Since everyone who has looked at or written a resume has a pretty good idea of what resumes contain, there was no mystery about what makes a Web page a resume. Thus, there was no advantage to machine-learning over the direct design of an algorithm to discover resumes.

### 1.1.3 Computational Approaches to Modeling

More recently, computer scientists have looked at **data mining as an algorithmic problem**. In this case, the **model of the data is simply the answer to a complex query about it**. For instance, given the set of numbers of Example 1.1, we might compute their average and standard deviation. Note that these values might not be the parameters of the Gaussian that best fits the data, although they will almost certainly be very close if the size of the data is large.

There are many different approaches to modeling data. We have already mentioned the possibility of constructing a statistical process whereby the data could have been generated. Most other approaches to modeling can be described as either

1. Summarizing the data succinctly and approximately, or

---

<sup>1</sup>This startup attempted to use machine learning to mine large-scale data, and hired many of the top machine-learning people to do so. Unfortunately, it was not able to survive.

2. Extracting the most prominent features of the data and ignoring the rest.

We shall explore these two approaches in the following sections.

#### 1.1.4 Summarization

One of the most interesting forms of **summarization** is the PageRank idea, which made Google successful and which we shall cover in Chapter 5. In this form of Web mining, **the entire complex structure of the Web is summarized by a single number for each page**. This number, the “PageRank” of the page, is (oversimplifying somewhat) the probability that a random walker on the graph would be at that page at any given time. The remarkable property this ranking has is that it reflects very well the “importance” of the page – the degree to which typical searchers would like that page returned as an answer to their search query.

Another important form of summary – **clustering** – will be covered in Chapter 7. Here, data is viewed as points in a multidimensional space. **Points that are “close” in this space are assigned to the same cluster**. The clusters themselves are summarized, perhaps by giving the centroid of the cluster and the average distance from the centroid of points in the cluster. These cluster summaries become the summary of the entire data set.

**Example 1.2:** A famous instance of clustering to solve a problem took place long ago in London, and it was done entirely without computers.<sup>2</sup> The physician John Snow, dealing with a Cholera outbreak plotted the cases on a map of the city. A small illustration suggesting the process is shown in Fig. 1.1.

Figure 1.1: Plotting cholera cases on a map of London

---

<sup>2</sup>See [http://en.wikipedia.org/wiki/1854\\_Broad\\_Street\\_cholera\\_outbreak](http://en.wikipedia.org/wiki/1854_Broad_Street_cholera_outbreak).

The cases clustered around some of the intersections of roads. These intersections were the locations of wells that had become contaminated; people who lived nearest these wells got sick, while people who lived nearer to wells that had not been contaminated did not get sick. Without the ability to cluster the data, the cause of Cholera would not have been discovered.  $\square$

### 1.1.5 Feature Extraction

The typical feature-based model looks for the most extreme examples of a phenomenon and represents the data by these examples. If you are familiar with Bayes nets, a branch of machine learning and a topic we do not cover in this book, you know how a complex relationship between objects is represented by finding the strongest statistical dependencies among these objects and using only those in representing all statistical connections. Some of the important kinds of **feature extraction** from large-scale data that we shall study are:

1. **Frequent Itemsets**. This model makes sense for data that consists of “baskets” of small sets of items, as in the market-basket problem that we shall discuss in Chapter 6. We **look for small sets of items that appear together in many baskets, and these “frequent itemsets” are the characterization of the data that we seek**. The original application of this sort of mining was true market baskets: the sets of items, such as hamburger and ketchup, that people tend to buy together when checking out at the cash register of a store or super market.
2. **Similar Items**. Often, your data looks like a collection of sets, and the objective is **to find pairs of sets that have a relatively large fraction of their elements in common**. An example is treating customers at an on-line store like Amazon as the set of items they have bought. In order for Amazon to recommend something else they might like, Amazon can look for “similar” customers and recommend something many of these customers have bought. This process is called “collaborative filtering.” If customers were single-minded, that is, they bought only one kind of thing, then clustering customers might work. However, since customers tend to have interests in many different things, it is more useful to find, for each customer, a small number of other customers who are similar in their tastes, and represent the data by these connections. We discuss similarity in Chapter 3.

## 1.2 Statistical Limits on Data Mining

A **common sort of data-mining problem involves discovering unusual events hidden within massive amounts of data**. This section is a discussion of the problem, including “Bonferroni’s Principle,” a warning against overzealous use of data mining.

### 1.2.1 Total Information Awareness

In 2002, the Bush administration put forward a plan to mine all the data it could find, including credit-card receipts, hotel records, travel data, and many other kinds of information in order to track terrorist activity. This idea naturally caused great concern among privacy advocates, and the project, called TIA, or *Total Information Awareness*, was eventually killed by Congress, although it is unclear whether the project in fact exists under another name. It is not the purpose of this book to discuss the difficult issue of the privacy-security tradeoff. However, the prospect of TIA or a system like it does raise technical questions about its feasibility and the realism of its assumptions.

The concern raised by many is that if you look at so much data, and you try to find within it activities that look like terrorist behavior, are you not going to find many innocent activities – or even illicit activities that are not terrorism – that will result in visits from the police and maybe worse than just a visit? The answer is that it all depends on how narrowly you define the activities that you look for. Statisticians have seen this problem in many guises and have a theory, which we introduce in the next section.

### 1.2.2 Bonferroni's Principle

Suppose you have a certain amount of data, and you look for events of a certain type within that data. You can expect events of this type to occur, even if the data is completely random, and the number of occurrences of these events will grow as the size of the data grows. These occurrences are “bogus,” in the sense that they have no cause other than that random data will always have some number of unusual features that look significant but aren't. A theorem of statistics, known as the *Bonferroni correction* gives a statistically sound way to avoid most of these bogus positive responses to a search through the data. Without going into the statistical details, we offer an informal version, *Bonferroni's principle*, that helps us avoid treating random occurrences as if they were real. Calculate the expected number of occurrences of the events you are looking for, on the assumption that data is random. If this number is significantly larger than the number of real instances you hope to find, then you must expect almost anything you find to be bogus, i.e., a statistical artifact rather than evidence of what you are looking for. This observation is the informal statement of Bonferroni's principle.

In a situation like searching for terrorists, where we expect that there are few terrorists operating at any one time, Bonferroni's principle says that we may only detect terrorists by looking for events that are so rare that they are unlikely to occur in random data. We shall give an extended example in the next section.

### 1.2.3 An Example of Bonferroni's Principle

Suppose there are believed to be some “evil-doers” out there, and we want to detect them. Suppose further that we have reason to believe that periodically, evil-doers gather at a hotel to plot their evil. Let us make the following assumptions about the size of the problem:

1. There are one billion people who might be evil-doers.
2. Everyone goes to a hotel one day in 100.
3. A hotel holds 100 people. Hence, there are 100,000 hotels – enough to hold the 1% of a billion people who visit a hotel on any given day.
4. We shall examine hotel records for 1000 days.

To find evil-doers in this data, we shall look for people who, on two different days, were both at the same hotel. Suppose, however, that there really are no evil-doers. That is, everyone behaves at random, deciding with probability 0.01 to visit a hotel on any given day, and if so, choosing one of the  $10^5$  hotels at random. Would we find any pairs of people who appear to be evil-doers?

We can do a simple approximate calculation as follows. The probability of any two people both deciding to visit a hotel on any given day is .0001. The chance that they will visit the same hotel is this probability divided by  $10^5$ , the number of hotels. Thus, the chance that they will visit the same hotel on one given day is  $10^{-9}$ . The chance that they will visit the same hotel on two different given days is the square of this number,  $10^{-18}$ . Note that the hotels can be different on the two days.

Now, we must consider how many events will indicate evil-doing. An “event” in this sense is a pair of people and a pair of days, such that the two people were at the same hotel on each of the two days. To simplify the arithmetic, note that for large  $n$ ,  $\binom{n}{2}$  is about  $n^2/2$ . We shall use this approximation in what follows. Thus, the number of pairs of people is  $\binom{10^9}{2} = 5 \times 10^{17}$ . The number of pairs of days is  $\binom{1000}{2} = 5 \times 10^5$ . The expected number of events that look like evil-doing is the product of the number of pairs of people, the number of pairs of days, and the probability that any one pair of people and pair of days is an instance of the behavior we are looking for. That number is

$$5 \times 10^{17} \times 5 \times 10^5 \times 10^{-18} = 250,000$$

That is, there will be a quarter of a million pairs of people who look like evil-doers, even though they are not.

Now, suppose there really are 10 pairs of evil-doers out there. The police will need to investigate a quarter of a million other pairs in order to find the real evil-doers. In addition to the intrusion on the lives of half a million innocent people, the work involved is sufficiently great that this approach to finding evil-doers is probably not feasible.
